 Draft version February 27, 2009

ABSTRACT

Wavelet analysis can be used to measure the power spectrum of solar wind fluctuations along a line in any direction (θ, ϕ) with respect to the local mean magnetic field $\mathbf{B}_0$. This technique is applied to study solar wind turbulence in high-speed streams in the ecliptic plane near solar minimum using magnetic field measurements with a cadence of eight vectors per second. The analysis of nine high-speed streams shows that the reduced spectrum of magnetic field fluctuations (trace power) is approximately azimuthally symmetric about $\mathbf{B}_0$ in both the inertial range and dissipation range; in the inertial range the spectra are characterized by a power-law exponent that changes continuously from 1.6 ± 0.1 in the direction perpendicular to the mean field to 2.0 ± 0.1 in the direction parallel to the mean field. The large uncertainties suggest that the perpendicular power-law indices $3/2$ and $5/3$ are both consistent with the data. The results are similar to those found by Horbury et al. (2008) at high heliographic latitudes. Comparisons between solar wind observations and the theories of strong incompressible MHD turbulence developed by Goldreich & Sridhar (1995) and Boldyrev (2006) are not rigorously justified because these theories only apply to turbulence with vanishing cross-helicity although the normalized cross-helicity of solar wind turbulence is not negligible. Assuming these theories can be generalized in such a way that the 3D wavevector spectra have similar functional forms when the cross-helicity is nonzero, then for the interval of Ulysses data analyzed by Horbury et al. (2008) the ratio of the spectra perpendicular and parallel to $\mathbf{B}_0$ is more consistent with the Goldreich & Sridhar scaling $P_\perp/P_\parallel \propto \nu^{1/3}$ than with the Boldyrev scaling $\nu^{1/2}$. The analysis of high speed streams in the ecliptic plane does not yield a reliable measurement of this scaling law. The transition from a turbulent MHD-scale energy cascade to a kinetic Alfvén wave (KAW) cascade occurs when $k_\perp \rho_i \simeq 1$ which coincides with the spectral break. At slightly higher wavenumbers, in the dissipation range, there is a peak in the power ratio with $P_\perp/P_\parallel \gg 1$. The decay of this peak may be caused by the damping of KAWs which is predicted to occur near $k_\perp \rho_i \simeq 4$.

Subject headings: Solar wind — turbulence, magnetohydrodynamics, scaling laws

1. INTRODUCTION

In the presence of a strong mean magnetic field $\mathbf{B}_0$, MHD turbulence is spatially anisotropic: velocity and magnetic field fluctuations vary more rapidly in the direction perpendicular to $\mathbf{B}_0$ than parallel to $\mathbf{B}_0$. It is important to recognize that fluctuations at a given scale are most strongly affected by the *local* mean magnetic field at roughly 3 to 5 times that scale. When this scale dependence of the local mean magnetic field is taken into account, the anisotropy of the turbulence becomes scale dependent because the direction of the local mean magnetic field changes with scale. Thus, anisotropy is a local property of the turbulence that depends on both position and scale.

In light of this, it is natural to expect wavelet analysis to be an effective tool for the study of anisotropy in plasma turbulence. Wavelet analysis allows a signal $f(t)$ to be decomposed into components that are localized in both time and frequency (or wavelet scale). Therefore, unlike the Fourier transform, the wavelet transform is well adapted to the study of transient signals (Daubechies 1992). Because of these properties, wavelet analysis can be used to study the power spectrum of turbulent fluctuations as a function of the direction of the local mean magnetic field as first shown by Horbury et al. (2008) using solar wind data.

Horbury et al. (2008) studied a 30 day interval of 1 second magnetic field data acquired by the Ulysses spacecraft at

high heliographic latitudes during solar minimum conditions in 1995 at a heliocentric distance of ~ 1.4 AU. The high latitude flow of the solar wind at this time can be characterized as high speed, highly Alfvénic (large magnitude of the normalized cross-helicity), with the average magnetic field directed roughly radially outward at the largest scales. By binning the square amplitude of the wavelet coefficients at a given scale according to the direction of the local mean magnetic field $\mathbf{B}_0$ at that scale they estimated the average power as a function of frequency and of the direction of $\mathbf{B}_0$. They found that the power law index of inertial range fluctuations varies from approximately $5/3$ to approximately 2 as the angle θ between $\mathbf{B}_0$ and the average flow direction decreases from $\pi/2$ to 0 .

This was interpreted by Horbury et al. (2008) as evidence that the 3D wavevector spectrum of solar wind fluctuations has the form given in the Goldreich & Sridhar (1995) theory of strong incompressible MHD turbulence. This interpretation is somewhat paradoxical, however, because the Goldreich & Sridhar (1995) theory does not apply to turbulence with non-vanishing cross-helicity as is usually found in the solar wind. Nevertheless, the results are intriguing because they demonstrate that the power law index of solar wind fluctuations varies with the angle θ between the flow direction and the local mean magnetic field, at least for the one data record studied by Horbury et al. (2008). This has never been seen before. In fact, based on earlier work by Sari & Valley (1976) and possibly others, it is a common belief that the spectral exponent of solar wind fluctuations is independent of the angle θ ; a view confirmed in a recent study by Tessein et al. (2009).

However, the study by Tessein et al. (2009) does not take into account the scale dependence of the local mean magnetic field and this may explain, in part, why no dependence of the spectral exponents on θ was found in that study.

Near solar minimum, the solar wind in the ecliptic plane is composed of recurring high-speed streams interspersed with lower speed wind. These streams originate in equatorial coronal holes which extend from the polar regions of the sun to the equator (Zirker 1977; Schwenn 2006) and have physical characteristics that are similar to the high-speed, high-latitude, solar wind found above polar coronal holes near solar minimum. Therefore, the variation in the power law index seen in high latitude Ulysses data by Horbury et al. (2008) should also be present in high-speed streams in the ecliptic plane around solar minimum. The purpose of this study is to investigate this expectation using magnetometer data from NASA's two Stereo spacecraft and to interpret the results using anisotropic theories of incompressible MHD turbulence. It should be emphasized that the physical quantity measured in this study is the so called *reduced spectrum* which is an integral of the 3D wavevector spectrum over a plane perpendicular to the mean magnetic field (Matthaeus & Goldstein 1982; Podesta 2009).

2. DATA SELECTION

NASA's two identically equipped Stereo spacecraft, Stereo Ahead (STA) and Stereo Behind (STB), were launched on 25 October 2006. The spacecraft both follow an earth-like orbit with one spacecraft moving progressively ahead of the earth and the other moving progressively behind the earth. This study uses data from the Stereo flux gate magnetometer (Acuña et al. 2008) part of the IMPACT instrument (Luhmann et al. 2008). The data has a uniform cadence of 8 vectors per second and contains no data gaps or missing data over the time intervals studied here.

Between April 2007 and June 2008 the solar wind in the ecliptic plane consisted a succession of high-speed streams of varying amplitudes interspersed with low-speed wind—typical conditions near solar minimum. The data used in this study is restricted to high-speed streams; the leading and trailing edges of high-speed streams were usually excluded. High-speed streams of long duration with sustained high speeds were preferred over shorter lived more rapidly decaying streams because they provided larger contiguous samples of high speed wind. Streams were identified using plasma data, proton velocity and density, from the PLASTIC instrument on board the two Stereo spacecraft (Galvin et al. 2008). The high-speed streams analyzed in this study are displayed in Figure 1 and their properties are listed in Table 1. The length of each data record is typically 3 or 4 days.

Near solar minimum, high speed streams are produced by equatorial coronal holes and are believed to be similar to the high speed wind at high heliographic latitudes. A single stream is usually embedded in a single magnetic sector of the interplanetary magnetic field and contains no sector crossings. For the nine intervals listed in Table 1, this was checked using running averages of the magnetic field vector to create 2D scatter plots of the average values of (B_R, B_T) versus time. Averaging windows with durations of 20, 40, and 60 minutes were used and, for simplicity, the offset from the beginning of one averaging window to the beginning of the next window was half the window width. The data is assumed to be contained in a single magnetic sector if the scatter plot remains in the same quadrant, either the second (B_0 inward) or

the fourth (B_0 outward), for a majority of the time with no points or very few points in the opposite quadrant (inward or outward).

The only other criteria used in the data selection is the requirement that power spectra obtained by the wavelet analysis described below should form well defined power laws throughout the inertial range and at all angles of interest. In one instance, some of the spectra obtained using data from December 2007 showed unusual fluctuations and erratic points suggesting there may have been inadequate sampling of the power in some angle bins or unusual statistical fluctuations in the time series, possibly caused by solar wind transients. Therefore, this interval was discarded.

3. WAVELET ANALYSIS TECHNIQUE

3.1. Continuous wavelet transform

The continuous wavelet transform of a function $f(t)$ is defined by

$$F(s, t) = \int_{-\infty}^{\infty} |s|^{-1/2} \psi^* \left(\frac{\tau - t}{s} \right) f(\tau) d\tau, \quad (1)$$

where s is the wavelet scale, t is the time, $\psi(t)$ is the mother wavelet, $\int_{-\infty}^{\infty} |\psi(t)|^2 dt = 1$, and the asterisk '*' denotes the complex conjugate. The wavelet scale s is related to the Fourier frequency as discussed below. The continuous wavelet transform allows any square integrable function $f(t)$ to be written as a continuous superposition of scaled and time-shifted wavelets by means of the inversion formula (Daubechies 1992)

$$f(t) = \frac{1}{C} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} |s|^{-1/2} \psi \left(\frac{t - \tau}{s} \right) F(s, \tau) \frac{ds d\tau}{s^2} \quad (2)$$

provided

$$C = \int_{-\infty}^{\infty} \frac{|\hat{\psi}(\omega)|^2}{|\omega|} d\omega < \infty, \quad (3)$$

where

$$\hat{\psi}(\omega) = \int_{-\infty}^{\infty} \psi(t) e^{-i\omega t} dt \quad (4)$$

is the Fourier transform of $\psi(t)$. The distribution of energy in the (s, t) plane (related to the time-frequency plane) is indicated by the relation

$$\int_{-\infty}^{\infty} |f(t)|^2 dt = \frac{1}{C} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} |F(s, t)|^2 \frac{ds dt}{s^2}, \quad (5)$$

which is similar to Parseval's formula.

In the special case where $f(t)$ is real valued and $\hat{\psi}(\omega)$ vanishes for $\omega < 0$, the inversion formula takes the simplified form

$$f(t) = \frac{2}{C} \int_0^{\infty} \frac{ds}{s^2} \int_{-\infty}^{\infty} d\tau \operatorname{Re} \left[s^{-1/2} \psi \left(\frac{t - \tau}{s} \right) F(s, \tau) \right], \quad (6)$$

where C is given by (3). Note that only positive scales $s > 0$ are included in the integral (6). Parseval's relation (5) takes the form

$$\int_{-\infty}^{\infty} |f(t)|^2 dt = \frac{2}{C} \int_0^{\infty} \frac{ds}{s^2} \int_{-\infty}^{\infty} dt |F(s, t)|^2. \quad (7)$$

Equations (6) and (7) are derived in Appendix A.

FIG. 1.— Speed profiles obtained from the plasma instrument (PLASTIC) on Stereo. The time intervals used in the wavelet analysis lie between the two vertical lines. The labels 1 through 9 correspond to the time intervals in Table 1.

^b The fits used to determine the power law exponents as a function of the angle θ were performed over the frequency interval $\nu_1 < \nu < \nu_2$.

^c Power law index when $\theta \simeq 90$ degrees obtained from the results in Fig. 6.

^d Power law index over the frequency interval $10^{-3} < \nu < 10^{-1}$ Hz obtained using all data for the indicated time interval.

The mother wavelet used in this study is the Morlet wavelet

$$\psi(t) = \pi^{-1/4} [e^{i\omega_0 t} - e^{-\omega_0^2/2}] e^{-t^2/2}, \quad (8)$$

where, in this study, $\omega_0 = 6$. Its Fourier transform is

$$\hat{\psi}(\omega) = 2^{1/2} \pi^{1/4} [e^{-(\omega - \omega_0)^2/2} - e^{-\omega_0^2/2} e^{-\omega^2/2}]. \quad (9)$$

To leading order, the Morlet wavelet (8) is a Gaussian envelope modulated by a complex exponential. This form is chosen because it is well localized in both time and frequency with a small time-frequency uncertainty product. If small correction terms are introduced to make $\hat{\psi}(\omega)$ vanish for $\omega < 0$, then the inversion formula (6) may be used. The magnitude of these correction terms are small and can often be neglected in practice. For the Morlet wavelet (8), numerical evaluation of the constant C in equation (3) yields the value $C \simeq 1.06$ when $\omega_0 = 6$.

To relate the wavelet scale s of the Morlet wavelet to an equivalent Fourier frequency ω , recall that the mean frequency $\bar{\omega}$ of the function $\hat{\psi}(\omega)$ (assumed positive valued) satisfies

$$\int_{-\infty}^{\infty} (\omega - \bar{\omega}) \hat{\psi}(\omega) d\omega = 0. \quad (10)$$

Substituting the function (9) into this equation shows that $\bar{\omega} \simeq \omega_0$ is an accurate approximation when $\omega_0 \gg 1$. Because the Fourier transform of the scaled wavelet is proportional to $\hat{\psi}(s\omega)$, it follows that the wavelet scale s corresponds to the mean Fourier frequency

$$\nu \simeq \frac{\omega_0}{2\pi s}, \quad (11)$$

where ν is the frequency in Hz and $\omega = 2\pi\nu$ is the frequency in radians per second. A more accurate approximation is obtained by computing the continuous wavelet transform of the function $f(t) = \cos(\omega t)$ and then finding the scale s where $|F(s, t)|^2$ is a maximum. To leading order, this yields the refined approximation derived in appendix B

$$\nu \simeq \frac{\omega_0}{2\pi s} \left(1 + \frac{1}{2\omega_0^2} \right). \quad (12)$$

3.2. Practical implementation

Suppose the function $f(t)$ vanishes outside the interval $0 < t < T$. If $f(t)$ is sampled at the discrete times $t_n = n\Delta t$, where $\Delta t = T/N$ and $n = 0, 1, 2, \dots, N-1$, then the wavelet transform (1) can be approximated by the Riemann sum

$$F(s, k\Delta t) \simeq \sum_{n=0}^{N-1} s^{-1/2} \psi^* \left[\frac{(n-k)\Delta t}{s} \right] f(n\Delta t) \Delta t. \quad (13)$$

This assumes that Δt is small enough to resolve the most rapid variations of the function $f(t)$. Likewise, the wavelet functions must be sufficiently well resolved at all scales s of interest (at least four samples per wave period). Let $s_m = s_0 a^m$, where s_0 is the smallest scale, $a > 1$, and $m = 0, 1, 2, \dots, M-1$. Then $\Delta s = s_{m+1} - s_m = (a-1)s_m$

and the inversion formula (6) can be approximated by

$$f(n\Delta t) \simeq \frac{2}{C} \sum_{m=0}^{M-1} \sum_{k=0}^{N-1} \text{Re} \left\{ s_m^{-1/2} \psi \left[\frac{(n-k)\Delta t}{s_m} \right] \times F(s_m, k\Delta t) \right\} \frac{(a-1)\Delta t}{s_m} \quad (14)$$

For this approximation to be valid the minimum and maximum values of s must include the smallest and largest timescales of the signal $f(t_n)$ and the grid size M along the s axis must be chosen large enough to provide adequate frequency resolution. To resolve the scaled wavelet function in equation (13) requires at least four samples per wavelet period at the minimum scale s_0 . This implies $\nu_{\max} \leq 1/(4\Delta t)$ and, therefore, using equation (11), $s_0 \geq 2\omega_0\Delta t/\pi \simeq 4\Delta t$. The maximum scale is typically less than the record length T .

From equation (7), the total energy of the signal is expressed in terms of the wavelet coefficients by the Parseval-like relation

$$\sum_{n=0}^{N-1} |f(t_n)|^2 \Delta t \simeq \frac{2}{C} \sum_{m=0}^{M-1} \sum_{n=0}^{N-1} |F(s_m, t_n)|^2 \frac{(a-1)\Delta t}{s_m}. \quad (15)$$

The right-hand side of equation (15) describes the distribution of signal energy in the time-frequency plane. In this study, the minimum scale is $s_0 = 2\omega_0\Delta t/\pi \simeq 4\Delta t$ and the maximum scale $s_{\max}$ is much less than the record length T in which case the right-hand side of (15) only includes contributions to the energy from scales less than or equal to $s_{\max}$.

The component of the signal at scale s_m makes a contribution to the total energy (15) given by

$$\frac{2}{C} \sum_{n=0}^{N-1} |F(s_m, t_n)|^2 \frac{(a-1)\Delta t}{s_m}. \quad (16)$$

The power spectral density $P(\nu)$ is defined such that $P(\nu)d\nu$ is the power in the frequency interval from ν to $\nu + d\nu$. Using the relation $d\nu \simeq \omega_0 ds/2\pi s^2$ and the fact that the average power is equal to the energy divided by the time, equation (16) implies

$$P(\nu_m) = \frac{4\pi\Delta t}{C\omega_0 T} \sum_{n=0}^{N-1} |F(s_m, t_n)|^2, \quad (17)$$

where the frequency ν_m is defined by equation (12) and T is the record length. This expresses the Fourier power spectrum (frequency spectrum) in terms of the wavelet coefficients. For the vector field $\mathbf{B}(t)$, the total power is the sum of the power of the three orthogonal components so that, in equation (17), $|F(s, t)|^2 = |F_R(s, t)|^2 + |F_T(s, t)|^2 + |F_N(s, t)|^2$.

In practice, the wavelet coefficients $F(s_m, t_n)$ may be computed using the FFT. The right-hand side of equation (13) consists of a convolution of the sequence $f_n = f(t_n)$ with the sequence

$$g_n = \psi^*(-t_n/s). \quad (18)$$

Note the minus sign in the argument of the function $\psi^*(t)$. Recall that for periodic sequences of length L , the discrete

Fourier transform of the convolution

$$h_n = f_n * g_n = \sum_{m=0}^{L-1} f_m g_{n-m}, \quad n = 0, 1, 2, \dots, L-1, \quad (19)$$

is equal to $H_k = F_k G_k$ (Briggs & Henson 1995), where

$$F_k = \sum_{n=0}^{L-1} f_n \exp(-i2\pi kn/L), \quad k = 0, 1, 2, \dots, L-1, \quad (20)$$

is the discrete Fourier transform of the sequence f_n and the inverse transform is defined by

$$f_n = \frac{1}{L} \sum_{k=0}^{L-1} F_k \exp(+i2\pi kn/L), \quad n = 0, 1, 2, \dots, L-1. \quad (21)$$

The integer $L > N$ must be chosen to avoid aliasing (wrap around effects) at the largest wavelet scale s and is typically a power of 2 to speed up the FFT algorithm. The envelope of the scaled Morlet wavelet $\exp(-t^2/2s^2)$ has an approximate temporal duration of $6s$. Therefore, the required duration for the zero padding is $3s_{\max}$ and L must be chosen such that $(L - N)\Delta t \gtrsim 3s_{\max}$. Note that the sequence f_n is padded with zeros to length L , but g_n is not since g_n is defined by equation (18) for $-L/2 < n \leq L/2$ and for any length L . The wavelet coefficients (13) at a given scale s are computed as follows. Compute the FFT of f_n and g_n at that scale, form the product $F_k G_k$, inverse transform the sequence $F_k G_k$, and then multiply by $s^{-1/2} \Delta t$. The first N terms of the resulting sequence of length L yield the coefficients $F(s, t_n)$ for $n = 0, 1, 2, \dots, N-1$.

The implementation of the wavelet transform has been tested using synthetic data. The wavelet transform of a 1 Hz cosine wave $f(t) = \cos(\omega t)$ is shown in Figure 2. The upper panel shows the magnitude of the wavelet transform $|F(s_m, t_n)|^2$ obtained from the sequence $f_n = f(n\Delta t)$ using the sampling time $\Delta t = 1/200$ sec and a record length of 20 sec. The lower panel shows the exact solution $|F(s, t)|^2$ obtained by evaluating the integral (1) in closed form (Appendix B). Except for the transient near $t = 0$, the results for the wavelet transform agree with the exact solution. For this particular calculation the minimum scale is $s_0 \simeq 8\Delta t$, the maximum scale is $s = 5$ sec, and $M = 200$. The equivalent frequency range extends from $\nu = 0.19$ Hz to $\nu = 25$ Hz. The cosine wave is a useful test case and the frequency of the wave is easily changed to investigate the behavior of the numerical solutions as a function of frequency.

Many other tests were performed. One more example shall now be described. Consider a 20 sec signal $f(t)$ composed of a sum of 91 cosine waves having unit amplitude and random phases. The frequencies of the waves extend from 1 Hz to 10 Hz in increments of 0.1 Hz. The power spectrum of $f(t)$ is computed using both the wavelet transform (17) and the FFT which is used to compute a frequency spectrum or periodogram (smoothed or unsmoothed). The results in Figure 3 demonstrate the reasonable agreement between these two independent techniques. For the example shown in Figure 3, the wavelet transform was computed using the minimum scale $s_0 \simeq 4\Delta t$, the maximum scale $s = 5$ sec, and $M = 200$. The FFT spectrum shown in Figure 3 was obtained using a Papoulis smoothing window with a bandwidth

FIG. 2.— The wavelet transform of $f(t) = \cos(\omega t)$ obtained using a Morlet wavelet with $\omega_0 = 6$. The numerical results in the upper plot agree with the exact solution in the lower plot. The transient near $t = 0$ (upper plot) is an artifact of the numerical method.

FIG. 3.— The power spectra density (PSD) obtained using the wavelet transform (blue) and the FFT (red) for a signal $f(t)$ composed of 91 cosine waves having unit amplitude, random phases, and frequencies from 1 Hz to 10 Hz in increments of 0.1 Hz. The PSD equals 5 Hz^{-1} between 1 Hz and 10 Hz (dashed line).

of 0.1 Hz (Percival & Walden 1993).

4. ANALYSIS OF SOLAR WIND DATA

The primary goal of this study is to investigate how power is distributed as a function of both frequency ν and the direction (θ, ϕ) of the local mean magnetic field. The local mean magnetic field at time t_n and wavelet scale s is obtained by weighting the time series with a Gaussian curve centered at

time t_n . Thus, the mean magnetic field at time t_n and wavelet scale s is proportional to

$$\bar{B}_n(s) = \sum_{m=0}^{N-1} B_m \exp \left[-\frac{(t_n - t_m)^2}{2\lambda^2 s^2} \right] \quad (22)$$

where $B_n = B(t_n)$. The width of the scaled Gaussian curve as measured by its full width at $1/e$ of its maximum is $2^{3/2}\lambda s \simeq 2.8\lambda s$. The dimensionless parameter λ determines the timescale of the average and in this study $\lambda = 1$. The local mean magnetic field (22) defines a direction $(\mu, \phi)_n$ at each time step n , where $\mu = \cos(\theta)$. The average velocity of the solar wind lies approximately in the heliocentric radial direction defined as $\theta = 0$ or, equivalently, $\mu = 1$.

Note that the local mean magnetic field in the work of Horbury et al. (2008) does not contain the factor of 2 which appears in the exponent in equation (22). The duration or timescale of the average (22) is therefore slightly larger than that employed by Horbury et al. (2008). This extraneous factor is not expected to significantly change the results of the analysis.

The angular distribution of power may be defined in different ways depending on the physical quantity of interest. The power spectral density may be defined as a function of frequency and angle such that the integral over all solid angles and all frequencies is equal to the total power of the signal (energy/time). However, in the solar wind, the direction of the local mean magnetic field is unevenly distributed over the surface of the unit sphere. Consequently, for a given direction B_0 , the energy at a given frequency is the product of the *average* energy of the fluctuations at that frequency when the field points in a solid angle $d\Omega$ about the direction B_0 multiplied by the number of times the field B_0 points in that direction. To describe the distribution of energy of the fluctuations without the weighting caused by the uneven distribution of directions of the local mean magnetic field, it is necessary to use the *average* energy of the fluctuations at that frequency when the field points in a given direction (a given angle bin). This is the approach adopted by Horbury et al. (2008) and also the approach adopted in this study. These two distinct approaches are now described in detail.

4.1. Angular distribution of power

The power spectral density (17) may be decomposed into an angular distribution $P(\nu, \mu, \phi)$ such that the integral over the unit sphere yields the power spectral density at frequency ν . In discrete form this is written

$$\sum_{k=0}^{N_\mu-1} \sum_{\ell=0}^{N_\phi-1} P(\nu_m, \mu_k, \phi_\ell) \Delta\mu_k \Delta\phi_\ell = \frac{4\pi\Delta t}{C\omega_0 T} \sum_{n=0}^{N-1} |F(s_m, t_n)|^2, \quad (23)$$

where $\{\mu_k : k = 0, 1, 2, \dots, N_\mu\}$ is a partition of the interval $(-1, 1)$, $\{\phi_\ell : \ell = 0, 1, \dots, N_\phi\}$ is a partition of the interval $(0, 2\pi)$, and the quantity $P(\nu_m, \mu_k, \phi_\ell) \Delta\mu_k \Delta\phi_\ell$ is obtained by including only those terms on the right-hand side for which the direction $(\mu, \phi)_n$ at time n lies in the interval $\mu_k \leq \mu < \mu_{k+1}$ and $\phi_\ell \leq \phi < \phi_{\ell+1}$. It is also useful to define the angular distribution $P(\nu, \mu)$ such that

$$\sum_{k=0}^{N_\mu-1} P(\nu_m, \mu_k) \Delta\mu_k = \frac{4\pi\Delta t}{C\omega_0 T} \sum_{n=0}^{N-1} |F(s_m, t_n)|^2, \quad (24)$$

where $P(\nu_m, \mu_k) \Delta\mu_k$ includes only those terms on the right-hand side for which the direction $(\mu, \phi)_n$ at time n satisfies $\mu_k \leq \mu < \mu_{k+1}$. That is,

$$P(\nu_m, \mu_k) \Delta\mu_k = \frac{4\pi\Delta t}{C\omega_0 T} \sum_{\substack{n=0 \\ \mu_k \leq \mu < \mu_{k+1}}}^{N-1} |F(s_m, t_n)|^2. \quad (25)$$

The function $P(\nu, \mu)$ describes the distribution of power as a function of the frequency ν and angle θ between the mean magnetic field and the average flow direction of the solar wind. It is the natural way to define the power spectral density per unit frequency and per unit angle $d\mu$. Consistent with the definition of power spectral density, the total power is equal to the sum over all frequencies of $\Delta\nu_m$ times (24). Therefore, the contribution to the total power when the local mean field lies in a direction between μ_k and μ_{k+1} is the sum over m of $\Delta\nu_m$ times (25), where the mean field depends on the scale s_m . A different definition of the power spectral density is given in the next subsection.

4.2. Power spectrum as a function of θ

At a given scale, the number of times the local mean magnetic field B_0 points in a given direction r within a small solid-angle $d\Omega$ will vary depending on the direction of the unit vector r . Thus, the probability distribution of directions of B_0 on the surface of the unit sphere is not necessarily uniform. By summing the energy of the fluctuations at each time step t_n when B_0 points in a given direction r , the average power of the fluctuations when B_0 points in that direction is the total energy divided by the length of time B_0 points in that direction. This is the power spectral density of the fluctuations at a given frequency when the local mean magnetic field points in a given direction.

Thus, for an angle bin with direction (μ, ϕ) and solid angle $d\Omega \ll 4\pi$, the average power per unit frequency when the local mean magnetic field points in that direction $P(\nu, \mu, \phi)$ is defined by

$$P(\nu_m, \mu, \phi) = \frac{4\pi}{C\omega_0 N_{\text{bin}}} \sum_{\{n: (\mu, \phi)_n \in \text{bin}\}} |F(s_m, t_n)|^2, \quad (26)$$

where N_{bin} is the number of terms in the sum, that is, the number of times t_n for which the local mean field lies within the given solid-angle. The definition (26) is believed to be equivalent to that employed by Horbury et al. (2008) and it is also the definition used in the present study.

Note that the usual Fourier analysis of solar wind time series ignores the fact that the local mean field spends different lengths of time pointing in different directions. This uneven distribution of directions of B_0 on the surface of the unit sphere causes an uneven weighting of power in a standard Fourier spectral analysis. The spectral analysis based on equation (26) removes this uneven weighting by dividing by the number of times the local mean field points in a given direction. This is made possible by the fact that the wavelet transform is localized in both time and frequency and, in this respect, the wavelet transform is superior to the Fourier transform.

The solar wind data listed in Table 1 was analyzed by means of the wavelet transform (13) and the spectral decomposition (26). The analysis shows that for frequencies throughout

FIG. 4.— The number of bin counts for each angle bin at the frequency 0.716 Hz using the data from March 2008 and January 2008 in Table 1. The direction $\theta = 0$ is radially outward from the sun. Note that these two data sets are contained in opposite magnetic sectors (inward and outward).

the inertial range and the dissipation range, frequencies from 5×10^{-3} Hz to 2 Hz in the spacecraft frame, the power spectral density in equation (26) is roughly independent of the azimuthal angle ϕ as is expected for turbulence that is cylindrically symmetric about the local mean magnetic field. Therefore, instead of equation (26), it is more expedient to use the power spectral density as a function of angle defined by

$$P(\nu_m, \mu_k) = \frac{4\pi}{C\omega_0 N_{mk}} \sum_{\substack{n=0 \\ \mu_k \leq \mu < \mu_{k+1}}}^{N-1} |F(s_m, t_n)|^2, \quad (27)$$

where the sum on the right-hand side only includes those terms for which the direction $(\mu, \phi)_n$ at time n satisfies $\mu_k \leq \mu < \mu_{k+1}$ and N_{mk} is the number of all such terms. The function $P(\nu, \mu)$ describes the power spectral density as a function of the angle θ between the local mean magnetic field and the (radial) mean flow direction.

In this study, angle bins are defined by the partition $\theta_k = k\pi/30$, $k = 0, 1, 2, \dots, 30$, $\mu_k = \cos(\theta_k)$. The width of each angle bin is 6 degrees which is small enough to resolve the interesting behavior near the endpoints $\theta = 0$ and $\theta = \pi$, but large enough to usually provide a reasonable statistical sample at all angles of interest. Figure 4 is a typical example of the distribution of bin counts seen for the data in this study. The orientation of the interplanetary magnetic field, outward or inward, is also apparent from Figure 4. The maximum bin count coincides with the direction of the Parker spiral in each case. The distributions of bin counts was qualitatively and quantitatively similar at all frequencies from 5×10^{-3} Hz to 2 Hz. The number of bin counts in the parallel direction was typically 4%–9% of the maximum number of bin counts taken

FIG. 5.— The power spectral density versus frequency for angle bins centered at $\theta = 3$ (bottom), 9, 15, 21, ..., 93 degrees (top) computed using the February 2008 data in Table 1 by means of equation (27).

over all bins.

5. RESULTS

The power spectra $P(\nu, \mu)$ computed by means of equation (27) using the February 2008 data in Table 1 are shown in Figure 5. The different curves in Figure 5 correspond to different angle bins and have been offset vertically for easier viewing. The minimum and maximum wavelet scales are approximately 0.48 s and 200 s, respectively. The number of different scales is $M = 30$. The corresponding frequency range extends from approximately 5×10^{-3} Hz to 2 Hz in the spacecraft frame. The transition from the low-frequency inertial range to the high-frequency dissipation range is indicated by the change in spectral slope around 0.4 Hz, a typical break-frequency near the orbit of the earth at 1 AU.

Restricting attention to the range of frequencies called the inertial range, $\nu \lesssim 0.2$ Hz, linear least squares fits are performed in log-log space to find the best fit power-law exponents. For a given data record, the frequency range used to obtain the fits is the same for all angles. But, for each data record in Table 1 a different frequency range is used to fit the data. This was necessary because of occasional outliers in the spectra, usually at the lowest frequencies, which can significantly effect the power law fits. Such outliers are partly

attributable to the smaller bin count at extreme angles and low frequencies. The frequency ranges used to fit the data are listed in Table 1. An example of the power-law fits are shown by the red line segments in Figure 5 which have been drawn so that they cover the precise frequency interval used to determine the fit.

The dependence of the inertial range power-law exponents on the angle θ are shown in Figure 6. For outward magnetic sectors, the power-law exponent changes from roughly 2 to 1.6 as the angle θ increases from 0 to 90 degrees. The results are qualitatively similar in every case. For inward magnetic sectors, the power-law exponent changes from roughly 2 to 1.6 as the angle θ decreases from 180 to 90 degrees. Once again, the results are qualitatively similar in every case. The error bars for the power law exponents in Figure 6 are 99% confidence intervals based on linear regression analysis of the data on a log-log plot, they are not standard deviations.

Near $\theta = 0$ in outward sectors and 180 degrees in inward sectors the power-law exponents are usually more uncertain as a consequence of the smaller number of statistical samples at these extreme angles. Nevertheless, the data indicate that the power law exponent when the mean field is parallel to the mean flow is approximately 2 ± 0.1 . The value of the power-law exponent when the mean field is perpendicular to the mean flow is approximately 1.6 ± 0.1 . In some cases the perpendicular power-law exponent is closer to $3/2$ than $5/3$, but the observations show significant variations from one angle bin to the next and from one data record to another so it is difficult to determine this value more precisely. Statistical studies may help answer this important question.

The power spectral density $P(\nu, \theta)$ as a function of angle θ is shown in the upper plot in Figure 7 which shows that the power is peaked near the perpendicular direction and that the anisotropy of the fluctuations described by the ratio of the perpendicular to the parallel power $P_{\perp}/P_{\parallel}$ increases as the frequency increases through the inertial range. The inertial range observations in Figure 7 are consistent with direct numerical simulations of incompressible MHD turbulence which show that in k -space the energy cascade is directed primarily perpendicular to the mean magnetic field and that the power anisotropy increases as the wavenumber increases (Shebalin et al. 1983; Oughton et al. 1994; Matthaeus et al. 1996). This behavior is also incorporated into phenomenological theories of strong incompressible MHD turbulence that take wavevector anisotropy into account in a fundamental way (Goldreich & Sridhar 1995, 1997; Boldyrev 2005, 2006; Lithwick et al. 2007; Beresnyak & Lazarian 2008; Chandran 2008; Podesta & Bhattacharjee 2009).

In the lower plot in Figure 7, the quantity $P_{\perp}$ is the average power in the two angle bins just below 90 degrees, bins 14 and 15, and $P_{\parallel}$ is the value in bin 1. The ratio $P_{\perp}/P_{\parallel}$ found in the present study is quantitatively similar to the results of Bieber et al. (1996) who found the ratio 1.4 (mean value) at 0.01 Hz and to the results of Horbury et al. (2008) who found a ratio of between 4 and 5 at 0.061 Hz at high heliographic latitudes near 1.4 AU. Smith et al. (2006) decomposed the magnetic field vector into orthogonal components perpendicular and parallel to the mean field and found that the average ratio of the power spectral density of the sum of the two perpendicular components to the parallel component, averaged from 8×10^{-3} Hz to 0.1 Hz, takes typical values around 10. It is not surprising that this *variance anisotropy* measured by

Smith et al. (2006) is quantitatively similar to the ratio $P_{\perp}/P_{\parallel}$ studied here, although the two physical quantities are different. Measurements similar to those of Smith et al. (2006) were also reported by Leamon et al. (1999) who found a mean ratio around 10 at the high frequency end of the inertial range.

An interesting new result is the observation that in the turbulent dissipation range the power ratio $P_{\perp}/P_{\parallel}$ often exhibits a double peak structure as shown in the lower plot in Figure 7. What is usually called the dissipation range begins at the spectral break (change in slope) in Figure 5, the point where the spectra in Figure 5 deviate from their linear fits, which occurs around 0.25 Hz for the data from February 2008. For the same data, the lower plot in Figure 7 shows that the ratio $P_{\perp}/P_{\parallel}$ decreases, attains a local minimum at around 0.4 Hz, and then increases again. What is most interesting is that it exhibits a prominent peak of large magnitude near 1 Hz before decreasing significantly beyond 1 Hz. This feature has never been observed before. A prominent peak near 1 Hz is seen in all the intervals listed in Table 1.

According to one school of thought, the turbulent energy cascade of MHD-scale fluctuations makes a transition from an Alfvén wave cascade to a Kinetic Alfvén Wave (KAW) cascade at the perpendicular wavenumber $k_{\perp} \rho_i \simeq 1$ (Quataert 1998; Quataert & Gruzinov 1999; Leamon et al. 1999; Cranmer & van Ballegoijen 2003; Howes 2008; Howes et al. 2008; Schekochihin et al. 2008, 2007). Observational evidence for such a transition in the solar wind is found in the measurements of Bale et al. (2005) which show the phase speed of the waves in this regime are consistent with the dispersion relation for KAWs. For the February 2008 data in the present study, the wavenumber such that $k_{\perp} \rho_i \simeq 1$ occurs at the observed spacecraft frequency $\nu_{sc} = V_{sw}/\lambda_{\perp} \simeq 0.5$ Hz. Thus, the onset of the KAW cascade occurs near the spectral break (~ 0.3 Hz) and also near the location of the local minimum in the lower plot in Figure 7. The observations in the lower plot in Figure 7 show that the ratio $P_{\perp}/P_{\parallel}$ increases as the frequency increases from 0.5 Hz, reaches a peak around 1 Hz, and then decreases rapidly near 2 Hz. The observed peak with the property $P_{\perp}/P_{\parallel} \gg 1$ demonstrates the perpendicular nature of the cascade in the dissipation range which is consistent with the existence of a kinetic Alfvén wave cascade in this regime.

The rapid decrease in the power ratio $P_{\perp}/P_{\parallel}$ beyond 1 Hz could be due to the dissipation of kinetic Alfvén waves (KAWs). The linear dispersion relation for electromagnetic waves in a collisionless electron-proton plasma at thermal equilibrium contains two branches which correspond, in the limit $k_{\perp} \rightarrow 0$, to the left circularly polarized ion-cyclotron (Alfvén-cyclotron) wave and the right circularly polarized electron-cyclotron (magnetosonic-whistler) wave. Suppose that the magnetosonic-whistler can be neglected in the first order of approximation. For the relevant solar wind parameters $\beta_{\perp p} = 2$, $v_{th,p} = 75$ km/s, and $k_{\perp}/k_{\parallel} = 10$, the hot plasma dispersion relation shows that the damping of KAWs becomes strong, $\gamma T \simeq -1$, when $k_{\perp} \rho_i \simeq 4$. This corresponds to an observed frequency of 2 Hz where, assuming the wave amplitudes are sufficiently small, the kinetic Alfvén waves are extinguished. Strong damping of KAWs near 2 Hz may cause the attenuation of the peak in the lower plot in Figure 7. However, another contributing factor may be a population of parallel propagating waves as explained later in this

FIG. 6.— Power-law exponents as a function of the angle θ between the direction of the local mean magnetic field and the heliocentric radial direction (approximately the mean flow direction).

section.

The measured plasma parameters used to make the above estimates for the February 2008 data in Table 1 consist of the average solar wind speed $V_{\text{sw}} = 625$ km/s, proton density $n_p = 3 \text{ cm}^{-3}$, proton thermal speed $v_{th,p} = 75$ km/s, magnetic field magnitude $B = 4.2$ nT, and the Alfvén speed $V_A = 49$ km/s. Measurements of the electron core temperatures on the Stereo spacecraft are unavailable due to instrument problems (P. Schroeder, private communication 2008). The ratio $T_p/T_e = 2$ is a typical value in high-speed wind (Marsch 1991a; Schwenn 2006; Marsch 2006), however, here

it is assumed for simplicity that $T_p/T_e = 1$. The ratio $k_{\perp}/k_{\parallel} = 10$ in the last paragraph comes from the assumption that MHD-scale turbulence in the solar wind obeys the critical balance hypothesis so that $k_{\parallel}/k_{\perp} \sim \delta v_k/v_A$; solar wind measurements indicate that at the smallest inertial range scales $\delta v_k/v_A \sim 1/10$. The exact dispersion relation given by equations (10-57) and (10-66) in Stix (1992) were used to compute the damping rates and Gautschi's algorithm was used to compute the plasma dispersion function (Gautschi 1970). The root of the dispersion relation where the damping becomes strong, $\gamma T \simeq -1$, is given by $(\omega/\Omega_p)/(k_{\parallel}\rho_i) = 1.5602 - 0.2375i$, where $k_{\parallel}\rho_i = 0.4$, $k_{\perp}\rho_i = 4$, and the proton cyclotron fre-

FIG. 7.— The power spectral density $P(\nu, \theta)$ normalized to the value in the parallel direction $\theta_0 = 3$ degrees and plotted as a function of the angle θ between the measurement direction and the direction of the local mean magnetic field for three different inertial range frequencies (upper plot); February 2008 data. The anisotropy described by the ratio of the perpendicular to the parallel power, $P_{\perp}/P_{\parallel}$, increases as the frequency increases through the inertial range and a well defined peak is seen in the dissipation range at 1 Hz (lower plot). The red line fit is proportional to $\nu^{0.44}$.

quency is $\Omega_p/(2\pi) = 0.064$ Hz. It is known that damping coefficients can be sensitive to small changes in the distribution functions which are usually far from thermal equilibrium in the solar wind. Therefore, the above calculation of damping coefficients of KAWs in the solar wind is subject to possibly large errors.

Another noteworthy feature in the lower plot in Figure 7 is the decrease of the ratio $P_{\perp}/P_{\parallel}$ around the spectral break and the local minimum near 0.4 Hz. This arises from an increase in the power $P_{\parallel}$ measured parallel to $\mathbf{B}_0$ relative to the power $P_{\perp}$ measured perpendicular to $\mathbf{B}_0$ and can also be seen in Figure 5 where it appears as a slight enhancement in the power spectrum near the spectral break in the bottom two curves. The probable cause is an enhanced population of nearly parallel propagating waves with wavenumber $k_{\parallel}\rho_i \sim 1$. Because the enhancement in the power spectra is only seen at small angles in Figure 5, $\theta \ll \pi/2$, it is suspected that the waves are parallel propagating. More extensive data analysis is necessary to confirm this. At the present time, the source of the waves is unknown. It is not known if they are part of the turbulence, somehow generated by the turbulence, or

whether they are independent of the turbulence. The waves could be generated in-situ by a kinetic instability. Coherent, parallel propagating waves around 0.5 Hz were frequently detected in the solar wind by Behannon (1976) who tentatively identified both ion-cyclotron and electron cyclotron waves in different data sets; similar observations have been made by Jian et al. (2008). Assuming the instability only exists for a narrow range of $k_{\parallel}$, then as $k_{\parallel}$ increases beyond this range $P_{\parallel}$ would be expected to decrease rapidly and this may explain why the ratio $P_{\perp}/P_{\parallel}$ in the lower plot in Figure 7 ramps up rapidly to form the peak near 1 Hz. These possibilities require further investigation.

Remarkably, a similar enhancement of proton density fluctuations in the solar wind near $k_{\parallel}\rho_i \sim 1$ has been reported by Neugebauer (1975, 1976). Hollweg (1999) has suggested these enhanced density fluctuations could be caused by the compressibility of KAWs in the case $k_{\perp} \gg k_{\parallel}$. However, if the enhancement in the present study is caused by *parallel* propagating waves, then it cannot be explained by Hollweg’s mechanism since, for parallel propagating waves, $k_{\perp} \ll k_{\parallel}$. Neugebauer et al. (1978) have suggested that the enhancement could be caused by right-hand ion cyclotron waves driven unstable by a proton thermal anisotropy with $T_{\parallel p} > T_{\perp p}$. While this could also explain the wavelet observations in the present study, other kinetic instabilities are also possible. The right-hand electromagnetic (whistler) wave instability driven by a proton beam (Montgomery et al. 1976) was dismissed by Neugebauer et al. (1978) because they believed in this case the unstable waves exist over a frequency range that is wider than what is seen in observations. The crucial quantity, however, is not the frequency in the plasma frame but the *wavelength* because the frequency observed in the spacecraft frame is determined by the rapid advection of the waves past the spacecraft (by the solar wind) and, therefore, is determined by the wavelength. Thus, by Taylor’s hypothesis, $\nu_{sc} = V_{sw}/\lambda$. Figure 4a in Montgomery et al. (1976) shows that the wavenumber range of the unstable waves could explain the observed density and/or magnetic field enhancements near $k_{\parallel}\rho_i \sim 1$.

The rapid attenuation of the peak around 2 Hz is another characteristic feature of the dissipation range data in the lower plot in Figure 7 that could be caused by an enhanced population of predominantly parallel propagating waves. Evidence comes from the power spectra in Figure 5 which show a “flattening” of the spectra near 2 Hz or, equivalently, $k_{\parallel}\rho_i \sim 4$. This flattening is more pronounced at small angles but is present in angle bins 1 through 8 indicating that if such waves are present, then they may propagate at angles as large as $\theta = 45$ degrees or so, even though the wave power is greatest for propagation near $\theta = 0$. It should be noted that the flattening of the power spectra cannot be caused by aliasing which would affect the spectra at all angles in the same way. Moreover, the underlying measurements were obtained with a cadence of 32 vectors per second. Further analysis of the data is necessary to investigate whether parallel propagating waves are present around 2 Hz and, if present, to characterize their properties which may be similar to those identified by Behannon (1976).

Moving now to the inertial range, an interesting observation in the lower plot in Figure 7 is the red trend line with slope 0.44 which is the best least-squares fit to the inertial range data between 0.025 Hz and 0.2 Hz. As discussed in the con-

clusions, the slope 1/2 is predicted by the phenomenological theory of Boldyrev (2006) and the slope 1/3 is predicted by the theory of Goldreich & Sridhar (1995). The best least-squares fit over the range from 0.01 Hz to 0.2 Hz yields the exponent 0.36 (not shown), however, it is not as good a fit as the exponent 0.44 over the range 0.025 Hz to 0.2 Hz. These considerations show that the scaling law is difficult to determine from the data. This difficulty is caused in part by the uncertainties in the ratio $P_{\perp}/P_{\parallel}$ which increase as the frequency decreases. These uncertainties can be reduced by using larger record lengths, but the record length is limited by the duration of the high speed stream. Further study is needed of this important scaling law.

6. COMPARISON TO ULYSSES RESULTS

It is of interest to compare the results of the present study with those obtained by Horbury et al. (2008). Unfortunately, the numerical results of Horbury et al. (2008) were not made available to us. Therefore, the analysis of Horbury et al. (2008) was repeated using the similar analysis technique developed in the present work.

The data consists of measurements of the solar wind magnetic field by the vector helium magnetometer on the *Ulysses* spacecraft (Balogh et al. 1992). The data spans a 30 day interval in 1995, day 100 through day 129, the same interval analyzed by Horbury et al. (2008). The data has a nominal 1 second cadence, however, some 1/2 s data and data gaps of various sizes are also present. The 1/2 s data is downsampled to 1 s and all data gaps are filled using linear interpolation to give a continuous time series with a 1 second cadence. This is necessary to compute convolutions using FFT techniques as described in section 4. The duration of the data gaps is negligible compared to the record length and, therefore, the linearly interpolated data makes a negligible contribution to the total power. The mean value of $\mathbf{B} = (B_R, B_T, B_N)$ taken over the entire record is (1.65, -0.74, -0.03) nT. The mean value of $B = |\mathbf{B}|$ is 3.07 nT and the r.m.s. value of $\mathbf{B}$ is $\delta B = 2.53$ nT. Thus, for the *Ulysses* data $\delta B/B \sim 1$. For each of the time intervals listed in Table 1, $\delta B/B \simeq 0.8$.

The wavelet analysis was performed in the same manner described in sections 4 and 5. Horbury et al. (2008) average the energy in each solid angle bin and then perform an azimuthal average with respect to ϕ . In the present study, intermediate averages over each solid angle bin were omitted and, in accordance with equation (27), only averages with respect to ϕ are performed. This has the advantage of yielding more robust statistics for angles in the parallel and perpendicular directions where the bin counts are relatively small. The results of the *Ulysses* analysis are shown in Figure 8.

Overall, the *Ulysses* results for the power-law indices in Figure 8 are qualitatively and quantitatively similar to the results for high-speed streams in the ecliptic plane shown in Figure 6. The power-law exponent closest to $\theta = 0$ in Figure 8 is not as close to 2 as in the results reported by Horbury et al. (2008), possibly because the bin size used here is larger. The power-law exponents approach values near 1.6 in the perpendicular direction, notably different than the value 5/3 reported by Horbury et al. (2008). When intermediate averages over each solid angle bin are omitted and averages are performed only with respect to ϕ , as in equation (27), the results take the form of the red curve in the upper plot in Figure 8. Note that the red curve gives a more monotonic functional form with

FIG. 8.— The power law exponents as a function of the angle θ between the local mean magnetic field and the mean flow direction (radial direction) for the 1995 *Ulysses* data, DOY 100–130 (upper plot). The black curve is obtained by averaging the power in each direction (μ, ϕ) separately and then performing a ϕ -average (upper plot). The red curve is obtained by averaging with respect to ϕ only which yields better statistics (upper plot). The ratio of the perpendicular to the parallel power, $P_{\perp}/P_{\parallel}$, increases approximately like $\nu^{1/3}$ as predicted by the Goldreich & Sridhar theory (lower plot). The linear least-squares fit yields the slope 0.35 ± 0.04 .

a perpendicular power law exponent closer to 1.58 than 1.67. The precise value of the parallel and perpendicular power-law exponents are important for comparisons with turbulence theories.

The ratio of power in the perpendicular direction to the power in the parallel direction, $P_{\perp}/P_{\parallel}$, is shown in the lower plot in Figure 8. Here, $P_{\parallel}$ is the power in angle bin 1, $P_{\perp}$ is the average power in bins 14 and 15, and the power is defined by equation (27). As described in more detail in the conclusions, the Goldreich & Sridhar (1995) theory predicts $P_{\perp}/P_{\parallel} \propto \nu^{1/3}$ and the Boldyrev (2006) theory predicts $P_{\perp}/P_{\parallel} \propto \nu^{1/2}$. The data in the lower plot in Figure 8 yield the power law fit $\nu^{0.35 \pm 0.04}$. This result is consistent with the Goldreich & Sridhar (1995) theory but inconsistent with the Boldyrev (2006) theory. These results are new and were not analyzed this way by Horbury et al. (2008).

7. COMPARISON TO POWER SPECTRUM USING ALL DATA

It is of interest to compare the results for the power law exponents in section 5 to the power law exponents obtained

FIG. 9.— The compensated power spectrum $\nu^\alpha P(\nu)$, trace spectrum, obtained using data for February 2008 in Table 1. The best fit power-law exponent over the frequency interval from 10^{-3} Hz to 10^{-1} Hz is $\alpha = 1.60$ (triangles). The exponent $\alpha = 5/3$ is not a good fit (circles). The horizontal line is drawn for comparison.

using all data. The power spectral density for each record (trace power) is computed using equation (17) which yields the same result as the power spectrum computed using standard FFT techniques (Percival & Walden 1993). The spectral exponent is obtained by a linear least squares fit over the interval from 10^{-3} Hz to 10^{-1} Hz. An example of the compensated spectrum for the February 2008 data in Table 1 is shown in Figure 9. The power law fits for the other intervals are qualitatively similar to that shown in Figure 9. A summary of the power law exponents for each interval are listed in Table 1.

The power law exponent for each interval (all data) is in approximate agreement with the power-law exponents observed over the range of angles between $\theta = \pi/2$ and the direction of the Parker spiral. This is to be expected because observations in Figure 6 show that the power law exponent is approximately constant between $\theta = \pi/2$ and the direction of the Parker spiral and the amplitude of the power spectrum is a maximum roughly when $\theta = \pi/2$. Furthermore, the fact that the direction of the local mean magnetic field is most often found near the direction of the Parker spiral means that the Fourier spectrum for all data is more heavily weighted by those fluctuations occurring when B_0 lies near the Parker spiral direction. Unfortunately, the large uncertainties for the exponents in Figure 6 preclude more precise comparisons of the power law exponents as a function of angle θ and the power law exponents obtained using all data.

8. DISCUSSION AND CONCLUSIONS

8.1. Summary

Wavelet analysis of solar wind data obtained at high heliographic latitudes by the Ulysses spacecraft led Horbury et al. (2008) to conclude that in the inertial range the power-law exponent of solar wind magnetic field fluctuations changes from approximately $5/3$ to approximately 2 as the angle θ between the local mean magnetic field and the mean flow direction decreases from $\pi/2$ to 0 . The similarity between high-speed solar wind at high latitudes and high-speed streams in the ecliptic plane around solar minimum suggests that a similar effect

should exist for power-law exponents in high-speed streams. The results of this study confirm this expectation.

Each of the nine high-speed streams analyzed in this study showed a decrease in the power-law exponent from 2 ± 0.1 to 1.6 ± 0.1 as the angle θ increases from 0 to $\pi/2$ for streams embedded in outward-directed magnetic sectors (large scale B_0 pointing away from the sun) and as the angle θ decreases from π to $\pi/2$ for streams embedded in inward-directed magnetic sectors (large scale B_0 pointing toward the sun).

In the inertial range, observations show that the power in the perpendicular direction $\theta = \pi/2$ is greater than the power in the parallel direction $\theta = 0$ or $\theta = \pi$ by factors ranging from approximately 2 at 0.01 Hz, near the middle of the inertial range to a factor of roughly 10 at 0.2 Hz, the upper end of the MHD-scale inertial range. Thus, it may seem that the power spectrum of the entire data record should have approximately the same power-law exponent as the spectrum in the perpendicular direction $\theta = \pi/2$. If true, then this provides a way to obtain more accurate estimates of the power-law exponent when $\theta = \pi/2$. However, as discussed in section 4.2, because the usual Fourier frequency spectrum is weighted by an uneven distribution of directions of the local mean magnetic field which is peaked in the direction of the Parker spiral, the power spectrum of the entire data record will likely have a power-law exponent that lies between the values observed in the directions $\theta = \pi/2$ and the direction of the Parker spiral, and probably closer to that in the direction of the Parker spiral because of its heavier statistical weight.

Interestingly, this effect could cause a spectrum with a perpendicular power-law exponent near $3/2$, as measured using the wavelet technique at $\theta = \pi/2$, to produce a power-law exponent that is close to 1.6 or even $5/3$ as measured by Fourier spectral analysis of the entire record. In fact, the results in Table 1 and in Figure 9 show that the power law exponent for the total magnetic energy is closer to 1.60 than 1.67 in all the intervals studied here. Therefore, it is possible that Fourier analysis techniques and Fourier frequency spectra which have been a standard tool in solar wind research for five decades may be giving misleading results for the power law index of turbulent MHD-scale fluctuations.

8.2. Comparison to previous work

It is of special interest to comment on the large statistical study by Tessein et al. (2009) who examined both high- and low-speed wind in the ecliptic plane near 1 AU and found no statistically significant dependence of the spectral index on the angle θ . The analysis technique employed by Tessein et al. (2009) was based on 1 hour intervals of solar wind data with a uniform cadence of 64 seconds. The spectral exponent for each 1 hour interval was determined by means of second order structure functions and the mean magnetic field for each interval, a 1 hour average, was used to bin the data according to the angle θ .

Tessein et al. (2009) may have been unable to detect any angle dependence of the spectral index, in part, because they neglected the scale dependence of the local mean magnetic field. This is important because the dynamically relevant mean magnetic field for fluctuations at the 10 second scale is not the mean magnetic field at the 1 hour scale. Note, however, that even if they did use a scale dependent mean magnetic field, the 1 hour intervals they use probably contain insufficient data to measure the spectral index near the parallel

direction $\theta = 0$, at least for the high-speed streams studied here. To demonstrate this, the wavelet analysis technique was applied to data intervals with a duration of 2 hours, subintervals of the data listed in Table 1. The 2 hour intervals are comparable in length to the 1 hour intervals used by Tessein et al. (2009). It was found that the two or three angle bins closest to $\theta = 0$ usually had insufficient data to form a power spectrum. Therefore, when restricted to such short record lengths, the wavelet technique is unable to detect changes in the spectral exponent near $\theta = 0$. Even with 8 Hz data, record lengths of a few hours do not contain sufficient data near the parallel direction to reveal the change in spectral index. Like the wavelet analysis, the analysis based on second order structure functions should be able to detect the angle dependence of the spectral index provided a large enough statistical sample is used and provided the scale dependence of the local mean magnetic field is taken into account.

There appears to be a discrepancy between the work reported here and the work of Dasso et al. (2005). Dasso et al. (2005) used data from the Advanced Composition Explorer (ACE) in the ecliptic plane near 1 AU to study correlation functions of solar wind fluctuations as functions of the angle θ and concluded that in high-speed streams the power in the fluctuations is dominated by wavevectors nearly parallel to the local mean magnetic field. This result of Dasso et al. (2005) appears to be inconsistent with the results presented here which show that for each of the high-speed streams investigated $P_{\perp}/P_{\parallel} > 1$ throughout the inertial range, that is, the power when the spacecraft traverses a path perpendicular to B_0 is greater than the power when the spacecraft traverses a path parallel to B_0 . This implies that power in the 3D wavevector spectrum is dominated by fluctuations with $k_{\perp} \gg k_{\parallel}$. This is also a well known feature of MHD turbulence with a strong mean magnetic field (Shebalin et al. 1983; Oughton et al. 1994; Matthaeus et al. 1996). It should be noted that the study of Dasso et al. (2005) encompasses larger inertial range scales than those considered here. However, it is not known if this can explain the discrepancy.

Hamilton et al. (2008) studied the variance anisotropy of magnetic field fluctuations $(\delta B_{\perp})^2/(\delta B_{\parallel})^2$, the ratio of the power in the two components of the magnetic field vector perpendicular to B_0 to the component parallel to B_0 . Their results show that for $\beta_p \sim 1$ the ratio $(\delta B_{\perp}/\delta B_{\parallel})^2$ takes typical values between 1 and 5, both in the inertial range and dissipation range. Moreover, in the dissipation range this ratio is typically less than or equal to that in the inertial range indicating an increase in the parallel component relative to the perpendicular components. This behavior is qualitatively consistent with theoretical predictions for KAWs (Hollweg 1999). The power ratio $P_{\perp}/P_{\parallel}$ in the present study is different from the variance anisotropy investigated by Hamilton et al. (2008) because $P_{\perp}$ and $P_{\parallel}$ both represent the trace power (three vector components). The wavelet technique can easily be adapted to measure the powers of the magnetic field components and the associated variance anisotropy. This is an interesting avenue of investigation for future work.

8.3. Theoretical interpretation

The observed variations of the spectral exponent as a function of θ have a theoretical interpretation that sheds light on the 3D wavevector anisotropy of solar wind turbulence in high speed wind. Horbury et al. (2008) have suggested the results may be interpreted as evidence that solar wind turbulence is

characterized by a 3D wavevector spectrum of the form given in the Goldreich & Sridhar (1995) theory of strong incompressible MHD turbulence, a theory based in part on the fundamental work by Higdon (1984). This is because the functional form of the Goldreich-Sridhar spectrum implies that the reduced spectra, the spectra observed in the spacecraft frame, have power-law exponents of 5/3 and 2 in the perpendicular and parallel directions, respectively; see Tessein et al. (2009) for a derivation of this result. However, it should be noted that Boldyrev's (2006) theory of strong incompressible MHD turbulence gives a similar prediction with power-law exponents of 3/2 and 2 in the perpendicular and parallel directions, respectively; the appropriate form of the wavevector spectrum in this case is discussed by Podesta (2009). The analysis of solar wind data shows that the perpendicular power-law exponents 3/2 and 5/3 cannot be distinguished from the data because of experimental uncertainties. Therefore, it may be premature to draw inferences regarding agreement with one or another theory.

Simulations of incompressible MHD turbulence suggest that Boldyrev's scaling applies in the presence of a strong mean magnetic field such that $\delta b \ll B_0$, where δb is the r.m.s. level of the turbulence and B_0 is the magnitude of the mean magnetic field (Mason et al. 2006, 2008). These and other simulations also suggest that the scaling may revert to the Goldreich-Sridhar scaling when the mean magnetic field is weak, $\delta b \gtrsim B_0$, although Boldyrev (2006) has speculated that his scaling may still apply in the inertial range provided the inequality $\delta b \ll B_0$ holds for fluctuation amplitudes δb within the inertial range. For both the Ulysses data analyzed by Horbury et al. (2008) and the high-speed streams analyzed here, the r.m.s. level of the turbulence satisfies $\delta b \sim B_0$ while at the smallest inertial range scales $\delta b \ll B_0$. Observations of the power ratio $P_{\perp}/P_{\parallel}$ in Figure 8 show that for the Ulysses data the Goldreich-Sridhar scaling gives a better fit than the Boldyrev scaling. Therefore, observations of this one time interval indicate that the Goldreich-Sridhar scaling is more consistent with the data even though $\delta b \ll B_0$ at the smallest inertial range scales. The scaling law of the power ratio $P_{\perp}/P_{\parallel}$ for high-speed streams in the ecliptic plane is difficult to determine because there is insufficient data to obtain reliable measurements at low frequencies. This problem can be resolved by using longer record lengths, however, the record length is limited by the lifetime of the streams.

From a theoretical point of view, it is important to realize that neither of the above theories can be applied to solar wind turbulence, even if incompressibility is a reasonable first approximation for the description of large MHD-scale solar wind fluctuations. This is because the theories of Goldreich & Sridhar (1995) and Boldyrev (2006) both assume that the cross-helicity of the turbulence vanishes, a point also made explicit by Higdon (1984), an assumption that is usually not satisfied in the solar wind (Marsch & Tu 1990; Marsch 1991b). A generalization of these theories to turbulence with nonvanishing cross-helicity is required to provide the proper foundation for comparisons between turbulence theory and solar wind observations. In particular, the theoretical form of the 3D wavevector spectrum of the two Elsasser spectra E^+ and E^- is needed.

Lithwick et al. (2007) have extended the theory of Goldreich & Sridhar (1995) to imbalanced turbulence, that is, turbulence with nonvanishing cross-helicity. In the theory

of Lithwick et al. (2007) the parallel correlation lengths of plus and minus Elsasser wavepackets are equal, that is, $\lambda_{\parallel}^+ = \lambda_{\parallel}^-$. However, this is inconsistent with the existence of different cascade times for the plus and minus Elsasser wavepackets as found in the theory. This inconsistency is easily remedied and the perpendicular energy spectra of the two Elsasser fields still have the same $k_{\perp}^{-5/3}$ scaling found by Lithwick et al. (2007). With this modification, the energy cascades of the plus and minus Elsasser variables are both in a state of critical balance and the reduced spectra perpendicular and parallel to the mean magnetic field are predicted to scale like $k_{\perp}^{-5/3}$ and $k_{\parallel}^{-2}$, respectively. Likewise, in the generalizations of the theory of Boldyrev (2006) to imbalanced turbulence by Perez & Boldyrev (2009) and Podesta & Bhattacharjee (2009), the reduced spectra perpendicular and parallel to the mean magnetic field are predicted to scale like $k_{\perp}^{-3/2}$ and $k_{\parallel}^{-2}$, respectively. The solar wind observations of Horbury et al. (2008) and those presented here

support these theoretical predictions although they cannot yet distinguish the Goldreich & Sridhar scaling $k_{\perp}^{-5/3}$ from the Boldyrev scaling $k_{\perp}^{-3/2}$ based on power-law exponents alone.

A remarkable conclusion of this study is that single spacecraft measurements can be used to glean information about the wavevector anisotropy of solar wind turbulence. Whether the power spectrum measured in the direction perpendicular to the local mean magnetic field has an exponent of 5/3 or 3/2 is an important fundamental question that remains unanswered. Interestingly, the 3/2 spectrum for magnetic field fluctuations is not yet ruled out.

It is a pleasure to thank Amitava Bhattacharjee, Charles Smith, Bernard Vasquez, Sergei Markovskii, Mario Acuña, David Curtis, and Jean Perez for helpful discussions. I am especially grateful to S. Peter Gary for his interest in this work and for several helpful comments and suggestions.

APPENDIX

DERIVATION OF THE INVERSION FORMULA

Equation (7) is derived from equation (5) as follows. The Fourier transform of the continuous wavelet transform (1) is

$$\int_{-\infty}^{\infty} F(s, t) e^{-i\omega t} dt = |s|^{1/2} \hat{f}(\omega) \hat{\psi}^*(\omega s), \quad (\text{A1})$$

where $\hat{f}(\omega)$ and $\hat{\psi}(\omega)$ are the Fourier transforms of $f(t)$ and $\psi(t)$, respectively. Therefore, by Parseval's theorem for Fourier transforms,

$$\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} F(s, t) G^*(s, t) \frac{ds dt}{s^2} = \int_{-\infty}^{\infty} \frac{ds}{|s|} \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \hat{f}(\omega) \hat{g}^*(\omega) |\hat{\psi}(\omega s)|^2 \quad (\text{A2})$$

Assuming $\hat{\psi}(\omega) = 0$ for $\omega < 0$, the right-hand side of equation (A2) is equal to

$$\begin{aligned} \int_0^{\infty} \frac{ds}{|s|} \int_0^{\infty} \frac{d\omega}{2\pi} \hat{f}(\omega) \hat{g}^*(\omega) |\hat{\psi}(\omega s)|^2 + \int_{-\infty}^0 \frac{ds}{|s|} \int_{-\infty}^0 \frac{d\omega}{2\pi} \hat{f}(\omega) \hat{g}^*(\omega) |\hat{\psi}(\omega s)|^2 \\ = \int_0^{\infty} \frac{ds}{|s|} \int_0^{\infty} \frac{d\omega}{2\pi} [\hat{f}(\omega) \hat{g}^*(\omega) + \hat{f}(-\omega) \hat{g}^*(-\omega)] |\hat{\psi}(\omega s)|^2. \end{aligned} \quad (\text{A3})$$

If the functions $f(t)$ and $g(t)$ are real valued, then $\hat{f}(-\omega) = \hat{f}^*(\omega)$ and this becomes

$$= 2 \operatorname{Re} \int_0^{\infty} \frac{ds}{|s|} \int_0^{\infty} \frac{d\omega}{2\pi} \hat{f}(\omega) \hat{g}^*(\omega) |\hat{\psi}(\omega s)|^2. \quad (\text{A4})$$

Changing the order of integration and performing the integral with respect to s yields

$$= 2C \operatorname{Re} \int_0^{\infty} \frac{d\omega}{2\pi} \hat{f}(\omega) \hat{g}^*(\omega) = C \int_{-\infty}^{\infty} f(t) g(t) dt \quad (\text{A5})$$

(write the integral on the left-hand side as an integral from $-\infty$ to $+\infty$ and then apply Parseval's theorem). Now, from (A3), this is also equal to

$$2 \operatorname{Re} \int_0^{\infty} \frac{ds}{|s|} \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \hat{f}(\omega) \hat{g}^*(\omega) |\hat{\psi}(\omega s)|^2 = 2 \operatorname{Re} \int_0^{\infty} \frac{ds}{s^2} \int_{-\infty}^{\infty} dt F(s, t) G^*(s, t). \quad (\text{A6})$$

Hence,

$$2 \operatorname{Re} \int_0^{\infty} \frac{ds}{s^2} \int_{-\infty}^{\infty} dt F(s, t) G^*(s, t) = C \int_{-\infty}^{\infty} f(t) g(t) dt. \quad (\text{A7})$$

Setting $g(t) = \delta(t - \tau)$ yields equation (6) and setting $g = f$ yields equation (7).

WAVELET TRANSFORM OF $\cos(\omega t)$

Inserting $f(t) = \cos(\omega t)$ into equation (1) yields the continuous wavelet transform

$$F(s, t) = 2^{-1/2} \pi^{1/4} |s|^{1/2} [A \exp(i\omega t) + B \exp(-i\omega t)], \quad (\text{B1})$$

where

$$A = \exp[-(\omega s - \omega_0)^2/2] - \exp\{-(\omega s)^2 + \omega_0^2\}/2\}, \quad (\text{B2})$$

$$B = \exp[-(\omega s + \omega_0)^2/2] - \exp\{-(\omega s)^2 + \omega_0^2\}/2\}. \quad (\text{B3})$$

The distribution of energy in the (s, t) plane is given by the function

$$|F(s, t)|^2 = \frac{\pi^{1/2}}{2} |s| (A^2 + B^2) \left[1 + \frac{2AB}{A^2 + B^2} \cos(2\omega t) \right]. \quad (\text{B4})$$

It is easy to show that $A/B = -\exp(\omega\omega_0 s)$ and, therefore,

$$|F(s, t)|^2 = \frac{\pi^{1/2}}{2} |s| (A^2 + B^2) \left[1 - \frac{\cos(2\omega t)}{\cosh(\omega\omega_0 s)} \right]. \quad (\text{B5})$$

The last term in the square brackets is negligible when $\omega\omega_0 s \geq 3$, that is, it is negligible except at very small frequencies or small scales. With this approximation,

$$|F(s, t)|^2 \simeq \frac{\pi^{1/2}}{2} |s| (A^2 + B^2). \quad (\text{B6})$$

To find the scale s where this function attains its maximum, assume $s > 0$ and then differentiate this expression with respect to s and set the result equal to zero. This yields the equation

$$\phi(x) = \left(\frac{2x^2}{\omega_0^2} - 1 \right) \cosh(x) - x \frac{\cosh(3x/2)}{\sinh(x/2)} = 0, \quad (\text{B7})$$

where $x = \omega\omega_0 s$. This equation has exactly one root in the interval $0 < x < \infty$. It has already been assumed that $\cosh(x) \gg 1$ and, therefore, this may be approximated by the quadratic equation

$$\frac{2x^2}{\omega_0^2} - 2x - 1 = 0 \quad (\text{B8})$$

with solution $x \simeq \omega_0^2 + \frac{1}{2}$. Hence, the scale s where the wavelet transform of $\cos(\omega t)$ is a maximum is approximately

$$s = \frac{1}{\omega\omega_0} \left(\omega_0^2 + \frac{1}{2} \right). \quad (\text{B9})$$

This proves (12).
